#### SISCER Module 5

Part I: Basic Concepts for Binary Markers (Classifiers) and Continuous Biomarkers July 12-13, 2021 8:30-Noon PT / 11:30-3pm ET

Kathleen Kerr, PhD
Professor of Biostatistics
SISCER Director

University of Washington

#### Module Overview

- Part I: Introductory concepts
- Part II: Evaluating Risk Models
- Part III: Evaluating the Incremental Value of New Biomarkers
- Part IV: Guidance on Developing Risk Models
- Part V: Setting goals for early phase biomarker research
- Part VI: Prognostic vs. Predictive Biomarkers
- biomarker analysis in R (short demo)

#### Module Overview

- The focus of this module is concepts rather than statistical details
  - we will not derive hypothesis tests or distributional results
  - we <u>will</u> examine some mathematical expressions as we explore concepts

## Misconceptions about Biomarkers and Risk Models

- A large odds ratio implies that a biomarker is useful for prediction.
- A data analyst can identify the optimal threshold from an ROC curve.
- A data analyst can identify the optimal risk threshold from a Decision Curve.
- The best biomarker to improve a risk model is the one with strongest association with the outcome.
- To improve prediction, a new biomarker should be independent of existing predictors
- To assess whether to add new biomarker to a risk model, multiple stages of hypothesis testing are needed.
- We can often use biomarkers to identify which patients will benefit from treatment.

### Part I Topics

- Motivating and illustrative examples
- True and false positive rates (TPR, FPR)
- Predictive values (PPV, NPV)
- ROC curves and area under the curve (AUC)
- Risk models
- What is "personal risk"?

#### Part 1 Overview

- Some examples
- To start: 1 marker X is binary (a "test")
- We then move on: 1 marker X is continuous
- Multiple markers X, Y, ..., and risk model
   P(bad outcome | X, Y, ...)

#### What is a Marker?

- DEF: a quantitative or qualitative measure that is potentially useful to classify individuals for current or future status
  - current → diagnostic marker
  - future → prognostic marker
- Includes biomarkers measured in biological specimens
- Includes imaging tests, sensory tests, clinical signs and symptoms, risk factors

# What is the purpose of a classifier or risk prediction tool?

- To inform subjects about risk
- To help make medical decisions
  - Often: identify individuals with high risk –
    individuals at high risk of a clinical event have
    the greatest potential to benefit from an
    intervention that could prevent the event
  - Sometimes: identify individuals with low risk who are unlikely to benefit from an intervention
- To enrich a clinical trial with "high risk" patients

### Terminology and Notation

- "case" or "event" is an individual with the (bad) outcome
- "control" or "non-event" is an individual without the outcome

case	control
D=1	D=0
D	$\overline{D}$
D	N

### Terminology and Notation

- X, Y = potential predictors of D (biomarkers, demographic factors, clinical characteristics)
- Often: X is "standard" predictor(s) and Y is a new biomarker under consideration
- risk(X) = r(X) = P( D=1 | X )
   risk(X,Y) = r(X,Y) = P( D=1 | X, Y)
- prevalence =  $P(D=1) = \rho$  ("rho")

## What is risk(X)?

 risk(x) ≡ P( D=1 | X=x ) is the frequency of events/disease among the group with X = x

- Risk is simply a population frequency.
   "Personal risk" is not completely personal!
  - Will return to this at the end of Part I

# Example: Coronary Artery Surgery Study (CASS)

- 1465 men undergoing coronary arteriography for suspected coronary heart disease
- Arteriography is the "gold standard" measure of coronary heart disease
  - Evaluates the number and severity of blockages in arteries that supply blood to the heart
- Simple cohort study
- Possible marker: exercise stress test (EST)
- Possible marker: chest pain history (CPH)

## Example: Breast Cancer Biomarkers

- Women with positive mammograms undergo biopsy, the majority turn out to be benign lesions
- Provides motivation to develop serum biomarker to reduce unnecessary biopsies (EDRN – early detection research network)

## Example: Pancreatic Cancer Biomarkers

- 141 patients with either pancreatitis (n=51) or pancreatic cancer (n=90)
- Serum samples
- Two candidate markers:
  - A cancer antigen CA-125
  - A carbohydrate antigen CA19-9
- Which marker is better at identifying cancer?
- Is either marker good enough to be useful?

Wieand, Gail, James, and James Biometrika 1989

#### Example: Cardiovascular Disease

- Framingham study
- D = CVD event
- Y = high density lipoprotein
- X = demographics, smoking, diabetes, blood pressure, total cholesterol
- n = 3264,  $n_D = 183$

#### Simulated Data

- Artificial data are useful for exploring/illustrating methodology
- Next: artificial datasets we will use to illustrate some methods
  - Simulated data on DABS website
  - Simulated data from R packages rmda (risk model decision analysis) and BioPET
  - Normal and MultiNormal biomarker model

## Example: Simulated data on DABS website

- $n = 10,000, n_D = 1017$
- Y = continuous, 1-dimensional
- X = continuous, 1-dimensional
- Search "Pepe DABS" or <u>http://research.fhcrc.org/diagnostic-biomarkers-center/</u>
  - "simulated risk reclassification dataset"

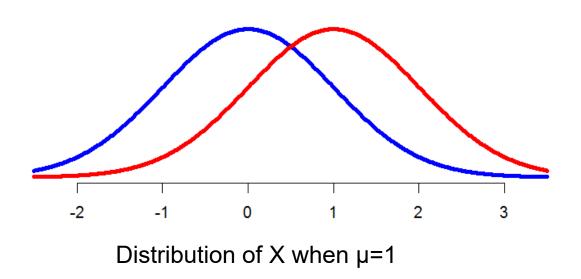

## Example: Simulated data in R packages

- $n = 500, n_D = 60$
- X = sex, smoking status, Marker1
- Y = Marker2
- These simulated data appear in software demo (not in module notes)

#### Normal Model with 1 Marker

 Biomarker X Normally distributed in controls and in cases

$$X \sim N(0,1)$$
 in controls  
  $X \sim N(\mu,1)$  in cases

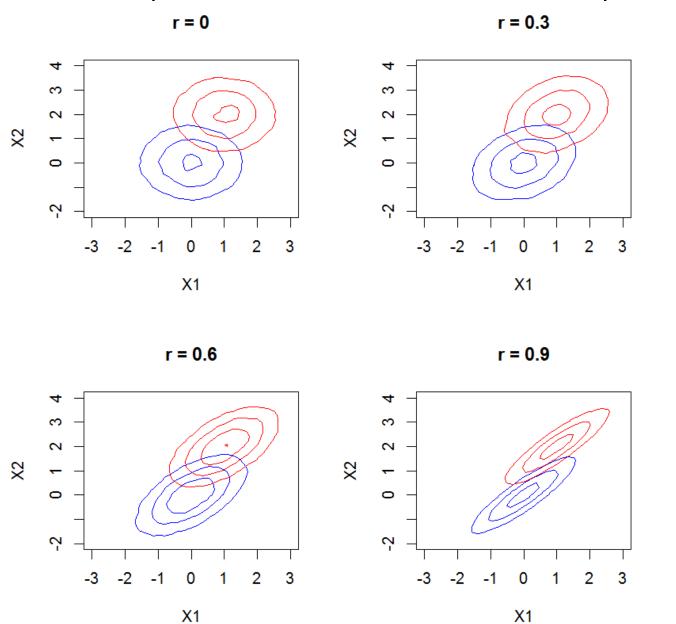

## Multivariate Normal Model with 2 Markers (Bivariate Normal)

 Biomarkers (X<sub>1</sub>, X<sub>2</sub>) are bivariate Normally distributed in controls and in cases

$$\vec{X} \sim MVN(\vec{0}, \Sigma)$$
 in controls  $\vec{X} \sim MVN(\vec{\mu}, \Sigma)$  in cases 
$$\Sigma = \begin{bmatrix} 1 & r \\ r & 1 \end{bmatrix}$$

In these examples  $X_1$  and  $X_2$  each have mean (0,0) in controls and mean (1,2) in cases. We can picture marker data in 2-dimensional space.

 Biomarkers (X<sub>1</sub>, X<sub>2</sub>) are bivariate Normally distributed in controls and in cases

$$\vec{X} \sim MVN(\vec{0}, \Sigma)$$
 in controls  $\vec{X} \sim MVN(\vec{\mu}, \Sigma)$  in cases

 This data model is useful in research because the logistic regression model holds for each marker and for both markers together.

```
logit P(D=1| X_1) is linear in X_1
logit P(D=1| X_2) is linear in X_2
logit P(D=1|X_1, X_2) is linear in X_1 and X_2
```

### Generalization: Multivariate Normal Model

• Biomarkers  $(X_1, X_2, ..., X_k)$  are multivariate Normally distributed in controls and in cases

$$\vec{X} \sim MVN(\vec{0}, \Sigma)$$
 in controls  $\vec{X} \sim MVN(\vec{\mu}, \Sigma)$  in cases

 The linear logistic model holds for every subset of markers

## QUANTIFYING CLASSIFICATION ACCURACY (BINARY MARKER OR "TEST")

### Terminology

- D = outcome (disease, event)
- Y = marker (test result)

	D=0	D=1
Y=0	true negative	false negative
Y=1	false positive	true positive

## Terminology

- D = outcome (disease, event)
- Y = marker (test result)

	D=0	D=1
Y=0	true negative	false negative
Y=1	false positive	true positive

### Terminology

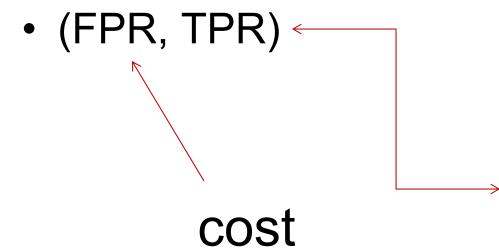

TPR = true positive rate = P[Y=1|D=1] = sensitivity

FPR = false positive rate = P[Y=1|D=0] = 1-specificity

FNR = false negative rate = P[Y=0|D=1] = 1-TPR

TNR = true negative rate = P[Y=0|D=0] = 1-FPR

Ideal test: FPR=0 and TPR=1

Later, we will consider the costs associated with false positives

#### benefit

Later, we will consider the benefits of identifying a true positive

# Coronary Artery Surgery Study (CASS)

**Coronary Artery Disease** 

		D=0	D=1
Exercise Stress Test	Y=0	327	208
Exercise 8	Y=1	115	815
	·	442	1023

FPR=115/442=26%

TPR=815/1023=80%

#### What about Odds Ratios?

- Odds ratios are very popular:
  - Because logistic regression is popular
  - Odds Ratio estimable from case-control study
  - OR≈relative risk for rare outcome

$$OR = \frac{TPR (1-FPR)}{FPR (1-TPR)}$$

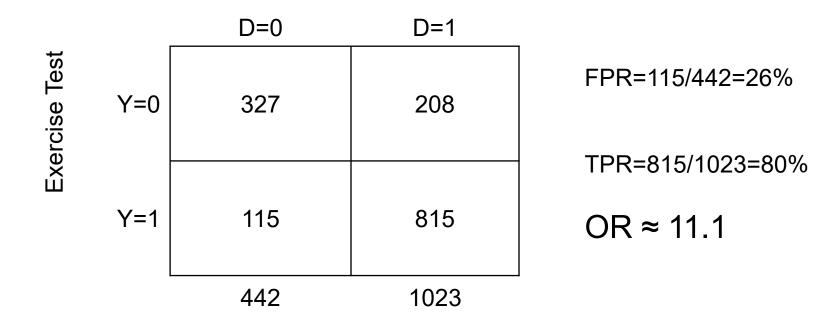

- Good classification (high TPR and low FPR)
  - → large odds ratio
- However, large odds ratio does NOT imply good classification!

#### Good classification → large odds ratio

E.g., TPR=0.8, FPR=0.10
$$OR = \frac{0.8 \times 0.9}{0.1 \times 0.2} = 36$$

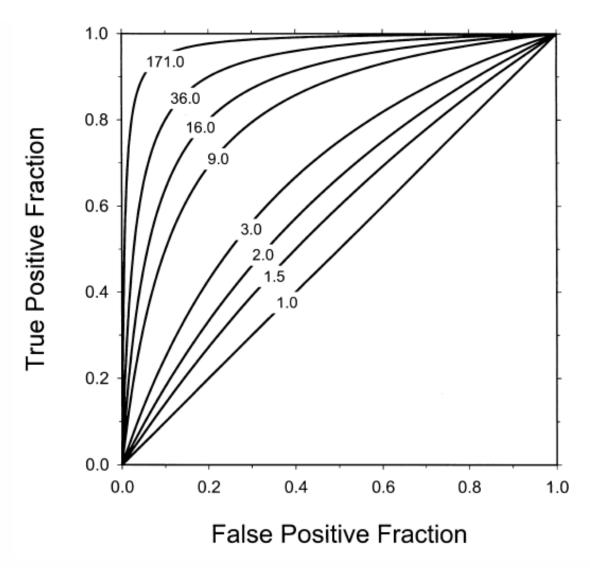

#### Coronary Artery Surgery Study (CASS)

OR is large but classification performance is not exceptional.

#### large odds ratio does NOT imply good classification!

**FIGURE 1.** Correspondence between the true-positive fraction (TPF) and the false-positive fraction (FPF) of a binary marker and the odds ratio. Values of (TPF, FPF) that yield the same odds ratio are connected.

- Need to report both FPR and TPR
- Collapsing into one number (e.g., OR) is not sufficient
  - important information is lost

#### Misclassification Rate

```
MR = error rate = P(Y \neq D)
= P(Y=0, D=1) + P(Y=1, D=0)
= \rho(1-TPR)+(1-\rho)FPR
```

- ρ is the prevalence P(D=1)
- only appropriate if the cost of false positives equals the cost of false negatives
- seldom appropriate in biomedical applications

#### Misclassification Rate

- There are two kinds of wrong decisions and the MR equates these.
  - Similarly, model "accuracy", which is 1—MR, equates the two types of errors.
- In order to be clinically relevant we must consider the harms of each kind of error
  - Part II

- FPR, TPR condition on true status (D)
- they address the question: "to what extent does the biomarker reflect true status?"

#### **Predictive Values**

Positive predictive value PPV=P(D=1|Y=1) Negative predictive value NPV=P(D=0|Y=0)

- condition on biomarker results (Y)
- address the question: "Given my biomarker value is Y, what is the chance that I have the disease?" This is the question of interest for patients and clinicians when interpreting the result of a biomarker or test

#### **Predictive Values**

PPV and NPV are functions of TPR and FPR and the prevalence ρ

$$PPV = \frac{\rho TPR}{\rho TPR + (1 - \rho)FPR}$$

$$NPV = \frac{(1 - \rho)(1 - FPR)}{(1 - \rho)(1 - FPR) + \rho(1 - TPR)}$$

- TPR, FPR are properties of a test, but PPV,
   NPV are properties of a test in a population
- For low prevalence conditions, PPV tends to be low, even with very sensitive tests

A serious disease affects 1 in 10,000 in a population.

A company markets a screening test as "98% accurate" because both sensitivity and specificity have been estimated to be 98%.

Those who test positive are recommended to undergo an invasive procedure for definitive diagnosis.

Should there be general screening for the patient population?

Disease affects 1 in 10,000 in a the population.

Test has sensitivity=specificity=98%.

A person from the population tests negative. What is the probability that person is truly not diseased?

A person from the population tests positive. What is the probability that person has the disease?

Disease affects 1 in 10,000 in a the population.

Test has sensitivity=specificity=98%.

What is the probability that person who tests negative is truly not diseased?

What is the probability that person who tests positive truly has the disease?

A serious disease affects 1 in 10,000 in a the relevant population.

A company markets a screening test as "98% accurate" because both sensitivity and specificity have been estimated to be 98%.

Those who test positive are recommended to undergo an invasive procedure for definitive diagnosis.

Should there be general screening for the patient population?

1 hour ago - Nutrition Diva Monica Reinagel

## False Discovery Rate

False Discovery Rate FDR=P(D=0|Y=1) =1 – PPV

"False Positive Rate" and "False Discovery Rate" sound similar, but they are very different

- •FPR: among all those who are not diseased, how many were called positive
- •FDR: among all those called positive, how many were not actually diseased.
- •We will not use or further discuss FDR.

CONTINUOUS MARKERS: ROC CURVES

#### Motivation

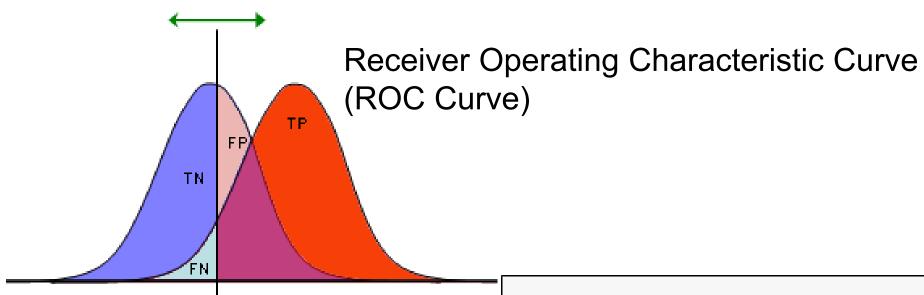

Most biomarkers are continuous

#### Convention

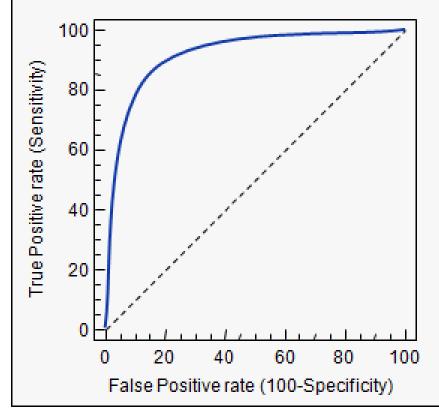

- Assume larger Y more indicative of disease
  - otherwise replace Y with -Y
- Formally: P(D=1 | Y) increasing in Y

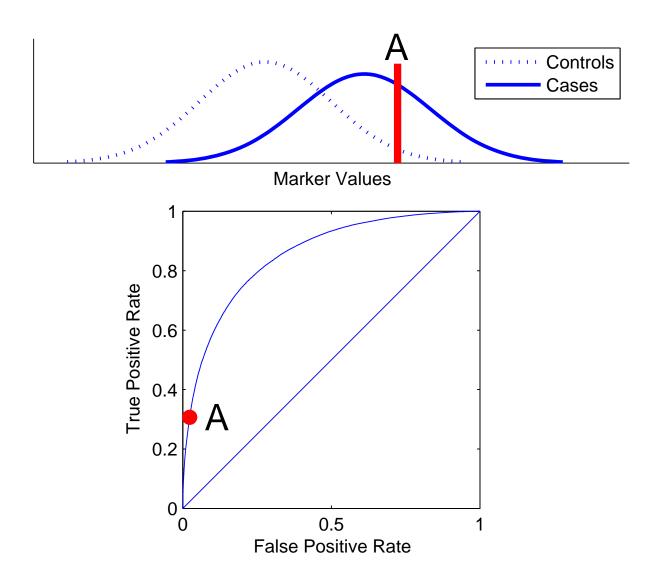

# Receiver Operating Characteristic (ROC) Curve

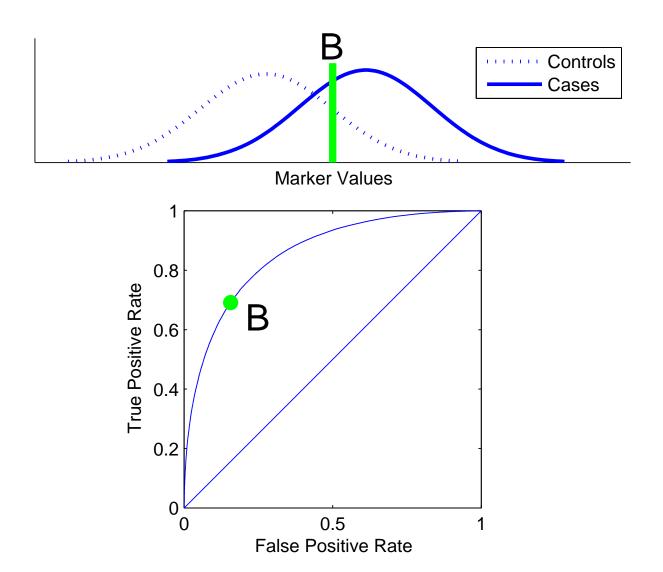

- generalizes (FPR, TPR) to continuous markers
- considers rules based on thresholds "Y≥c"
  - makes sense if P(D=1|Y) increasing in Y
- TPR(c)=P( $Y \ge c \mid D=1$ )
- $FPR(c)=P(Y \ge c \mid D=0)$
- ROC(·)={FPR(c), TPR(c); c in (-∞,∞)}

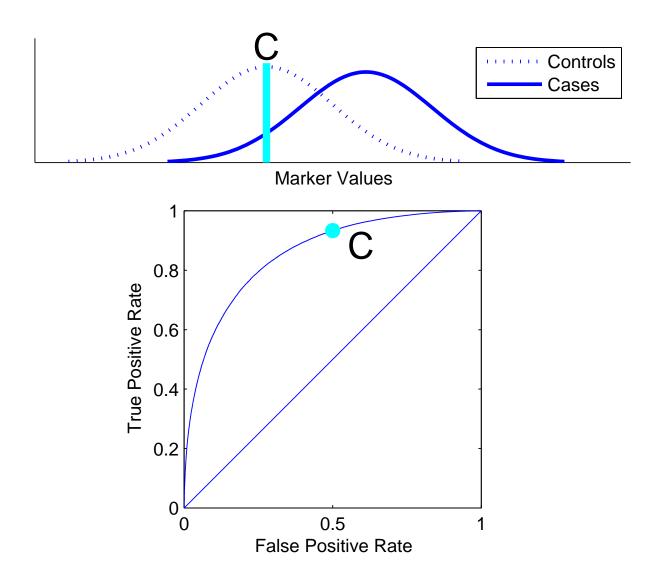

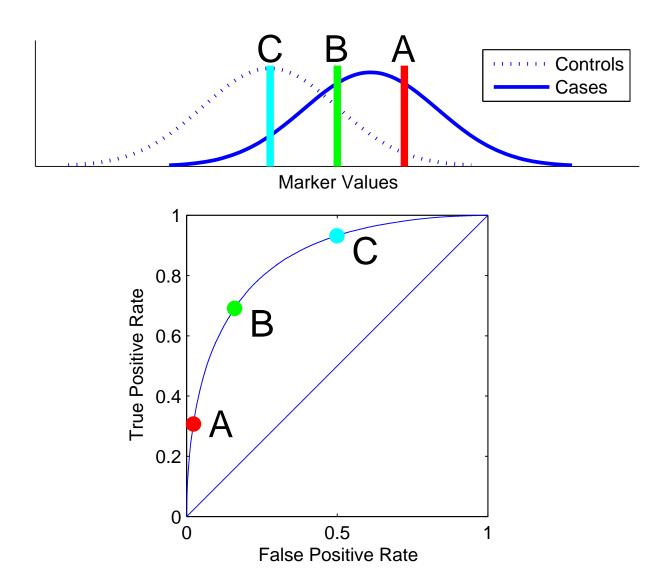

Each point on the ROC curve corresponds to a threshold for declaring "marker-positive."

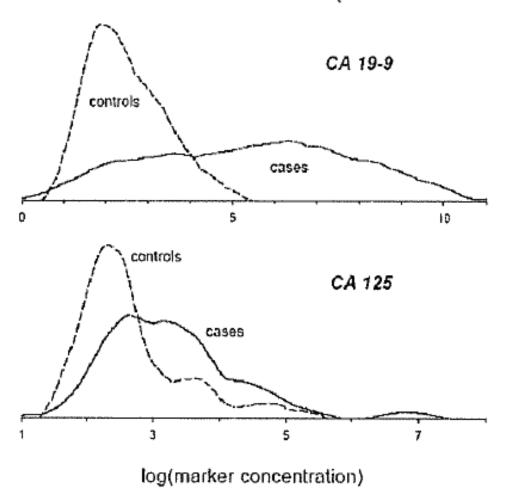

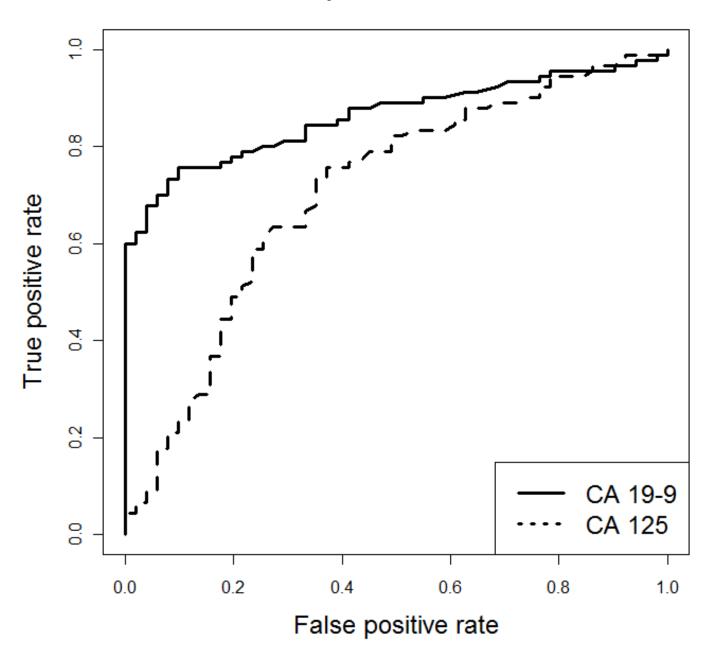

#### Properties of ROC curves

- non-decreasing from (0,0) to (1,1) as threshold decreases from c=∞ to c= -∞
- ideal marker has control distribution completely disjoint from case distribution; ROC through (0,1)
- useless marker has ROC equal to 45 degree line
- doesn't depend on scale of Y: invariant to monotone increasing transformations of Y
- puts different markers on a common relevant scale
- shows entire range of possible performance

#### Pancreatic cancer biomarkers (Wieand et al 1989)

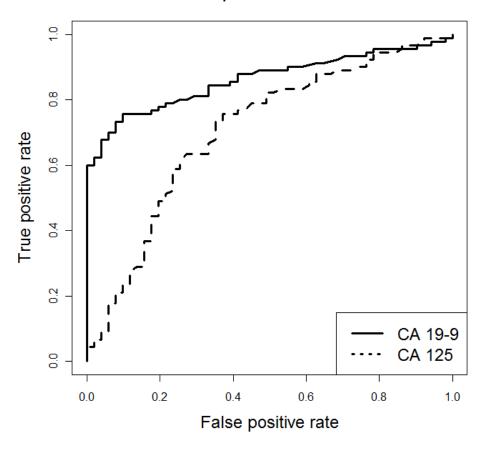

#### **ROC** curves for pancreatic cancer biomarkers

#### **ROC** curves for pancreatic cancer biomarkers

CA-19-9 appears to be the more accurate diagnostic biomarker for pancreatic cancer

- for most FPR, CA-19-9 has the better corresponding TPR
- for most TPR, CA-19-9 has the better corresponding FPR

#### **ROC** limitations

- ROC curve summarizes (FPR, TPR) across all possible cut-points for the continuous marker
  - Alternatively, (specificity, sensitivity)
  - Aids in assessing: How well can the marker discriminate between controls and cases?
- While useful, ROC curves do not contain crucial information
  - Prevalence
  - Value of TP, Cost of FP
- →There is no way to determine an optimal cut-point from an ROC curve

#### Summarizing ROC Curves: AUC

- AUC is <u>Area under ROC curve</u>
- AUC =  $_0\int^1 ROC(t) dt$  = average(TPR)
  - average is uniform over (0,1)
- Common summary of ROC curve
  - sometimes called the c-index or c-statistic
- ideal marker: AUC=1.0
- useless marker: AUC=0.5
- A single number summary of a curve is necessarily a crude summary
- Commonly used to compare biomarkers

## AUC: probabilistic interpretation

 For a randomly selected case D and a randomly selected control N,

$$AUC = P(Y_D > Y_N)$$

- Provides an interpretation for AUC beyond "area under ROC curve"
- AUC is interpretable, but its interpretations show that AUC is not clinically meaningful

#### **RISK PREDICTION**

#### Risk Model: Huntington's Disease

- Huntington's Disease is caused by the gene HTT on human chromosome 4. There is a CAG segment that is repeated 10-35 times in non-diseased individuals. If the segment is repeated 36-120+ times, a person develops\* Huntington's Disease in middle-age. The genetic abnormality is dominant — one abnormal gene causes disease.
  - \*40+ times: always develop HD
  - \*36-39 times: might not develop HD (ignoring this small possibility)

#### Risk Model: Huntington's Disease

- Relevant Population: Individuals with a biological parent who has Huntington's Disease
- Within this population, an individual has a 50% chance of developing HD depending on whether he or she inherited the abnormal or normal version of the gene from the affected parent.
- $P(D) = \frac{1}{2} = \rho$  in this population.

#### Risk Model: Huntington's Disease

- An individual can choose to have their HTT gene genotyped. Say HTT=0 means 0 copies of abnormal gene; HTT=1 means 1 copy of abnormal gene.
- P(D|HTT=0)=0%; P(D|HTT=1)=100%.
- The marker HTT *stratifies* the patient population (risk=50%) into the subgroup with 0% risk and the subgroup with 100% risk.

#### Risk model

- risk prediction model gives a risk based on a marker value or a combination of markers
- Predicted risks are in the interval [0,1] and interpreted as probabilities
- It is rare that a risk model is definitive like the HD example
  - In fact, because the genetic test for Huntington's Disease is definitive, we might not think about it as a risk model

#### Risk model examples

- Most risk models combine information from multiple risk factors
- E.g., Gail model for breast cancer risk
  - for use in women with no history of breast cancer
  - Estimates 5-year risk of breast cancer based on current age, age at menarche, age at first birth, family history, race.
- E.g., Framingham CHD risk score
  - Estimates risk of CHD based on age, sex, smoking status, total and HDL cholesterol, blood pressure

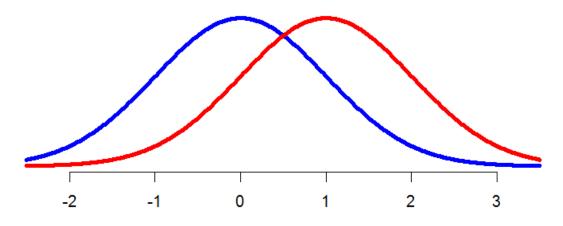

#### Risk model examples

- E.g. STS risk score for dialysis following cardiac surgery is formed via:
  - STS risk score =  $f(\alpha + \beta_1 \text{ Age} + \beta_2 \text{ Surgery Type} + \beta_3 \text{ Diabetes} + \beta_4 \text{ MI Recent} + \beta_5 \text{ Race} + \beta_6 \text{Chronic Lung Disease} + \beta_7 \text{ Reoperation} + \beta_8 \text{NYHA Class} + \beta_9 \text{ Cardiogenic Shock+ } \beta_{10} \text{Last Serum Creatinine})$

 Recall: risk(x) ≡ P( D=1 | X=x ) is the frequency of events among the group with marker values x

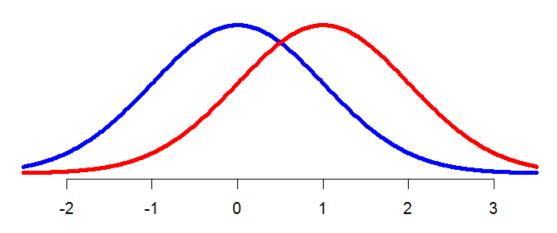

- "Personal risk" is not completely personal!
  - (next example)

- Suppose the prevalence of D in "Population A" is 1%
  - Without any additional information, the only valid risk prediction instrument is to assign everyone in the population risk=1%
- Suppose we have a marker X that tends to be higher in cases than controls

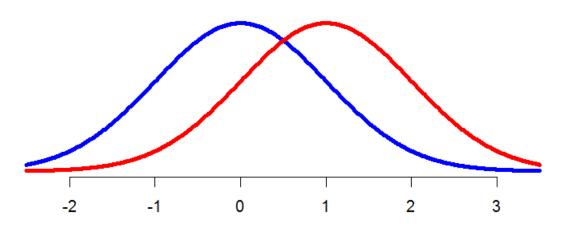

Distribution of marker X in controls (blue) and cases (red)

- Alice is an individual in Population A. Alice has X=1.
- We can calculate Alice's risk(X=1)≈1.6%
  - calculation uses Bayes' rule

Distribution of marker X in controls (blue) and cases (red)

- Suppose the marker acts exactly the same in Population B. The only difference between Populations A and B is that B has prevalence=10%.
- Betty, an individual in Population B, has X=1.
   Betty's risk is ≈15.5%

Distribution of marker X in controls (blue) and cases (red)

- "Personal risk" is a term that is prone to be misconstrued
- Risk <u>is personal</u> in the sense that it is calculated from personal characteristics
- However, <u>personal risk is not completely divorced</u>
   <u>from population characteristics</u>. The previous
   example shows that the population (specifically, the
   population prevalence) affects "personal" risk.

- Occasionally one hears mention of estimating a person's "individual risk" or "true personal risk."
- Frequentist statisticians cannot really claim to do so.
- One might claim John's "true risk" of a heart attack in the next 5 years is 7%. But we can only observe John having or not having a heart attack in the next 5 years. I cannot observe John having a heart attack in 7% of 5-year periods from now.
- The best I can objectively claim is that "among people with John's characteristics, 7% will have a heart attack in the next 5 years."
  - More than one way to define "people like John."

## Summary of Part I

- Example datasets
- FPR (1 specificity), TPR (sensitivity)
- PPV, NPV
  - function of FPR, TPR and disease prevalence
- ROC curves
- AUC
  - geometric interpretation as area under curve
  - probability interpretation
- A risk model gives population frequencies: risk(X)=P(D=1|X)

## Misconceptions about Biomarkers and Risk Models

- A large odds ratio implies that a biomarker is useful for prediction.
- A data analyst can identify the optimal threshold from an ROC curve.
- A data analyst can identify the optimal risk threshold from a Decision Curve.
- The best biomarker to improve a risk model is the one with strongest association with the outcome.
- To improve prediction, a new biomarker should be independent of existing predictors
- To assess whether to add new biomarker to a risk model, multiple stages of hypothesis testing are needed.
- We can often use biomarkers to identify which patients will benefit from treatment.
